DOUBLE-SLICING ASSISTED SUFFICIENT DIMENSION REDUCTION FOR HIGH DIMENSIONAL CENSORED DATA

BY SHANSHAN DING∗, WEI QIAN∗ AND LAN WANG†

University of Delaware∗ and University of Minnesota†

This paper provides a unified framework and an efficient algorithm for analyzing high-dimensional survival data under weak modeling assumptions. In particular, it imposes neither parametric distributional assumption nor linear regression assumption. It only assumes that the survival time $T$ depends on a high-dimensional covariate vector $X$ through low-dimensional linear combinations of covariates $\Gamma^T X$. The censoring time is allowed to be conditionally independent of the survival time given the covariates. This general framework includes many popular parametric and semiparametric survival regression models as special cases. The proposed algorithm produces a number of practically useful outputs with theoretical guarantees, including a consistent estimate of the sufficient dimension reduction subspace of $T \mid X$, a uniformly consistent Kaplan-Meier type estimator of the conditional distribution function of $T$ and a consistent estimator of the conditional quantile survival time. Our asymptotic results significantly extend the classical theory of sufficient dimension reduction for censored data (particularly that of Li et al. 1999) and the celebrated nonparametric Kaplan-Meier estimator to the setting where the number of covariates $p$ diverges exponentially fast with the sample size $n$. We demonstrate the promising performance of the proposed new estimators through simulations and a real data example.

1. Introduction. Literature on high-dimensional data analysis has experienced an explosion recently. However, there still exists relatively little work, particularly with theoretical guarantees, for analyzing high dimensional data with censored responses where new technical challenges arise. We are interested in studying the relationship between an event time $T$ and a $p$-dimensional vector of predictors $X = (X_1, \ldots, X_p)^T$. The event time $T$ may not be observed due to right censoring, such as patients dropout. Let $Y = \min(T, C)$ be the observed event time where $C$ denotes the censoring variable, and let $\delta = I(T \leq C)$ be the censoring indicator. The observed data consist of $(X_i, Y_i, \delta_i), i = 1, \ldots, n$. In this paper, we develop a general

Keywords and phrases: central subspace, sufficient dimension reduction, variable selection, censored data, ultrahigh dimension, nonparametric estimation
theory for analyzing such censored data in the setting where the number of covariates \( p \) can be much larger than the sample size \( n \). A distinguishable feature of our proposal is that we only impose a very general model framework instead of a specific model. In particular, we impose neither parametric distributional assumption nor linear regression assumption.

The basic modeling assumption we adopt is that \( T \) depends on \( X \) only through a few linear combinations of covariates \( \Gamma^T X \), where \( \Gamma \) is a \( p \times d \) (\( d \leq p \) ) matrix with \( d \) usually much smaller than \( p \). Alternatively, we write

\[
T \perp \perp X | \Gamma^T X,
\]

where \( \perp \perp \) stands for independence. The matrix \( \Gamma \) itself is not identifiable as for any \( d \times d \) nonsingular matrix \( A \), \( A^T \Gamma^T X \) also satisfies (1.1). Instead, we aim to estimate the smallest linear space spanned by the columns of \( \Gamma \), denoted by \( S_{T|X} \). In the dimension reduction literature, such a space is referred to as the central subspace, and is known to exist and be unique under mild conditions (Cook 1998).

Note that (1.1) is equivalent to the statement \( F(T \mid X) = F(T \mid \Gamma^T X) \), where \( F(T \mid X) \) and \( F(T \mid \Gamma^T X) \) are conditional distribution functions of \( T \) given \( X \) and \( \Gamma^T X \), respectively. To appreciate the flexibility of this general formulation, we observe that (1.1) encompasses many popular survival analysis model assumptions as special cases regarding \( T \mid X \).

- **Proportional hazards or Cox model**: \( h(t \mid X) = h_0(t) \exp(\beta^T X) \), where the hazard function \( h(t \mid X) = -\frac{d}{dt} \log Q(t \mid X) \) with \( Q(t \mid X) = 1 - F(t \mid X) \) being the conditional survival function. This model is equivalent to \( F(t \mid X) = 1 - \exp\{-H_0(t)e^{\beta^T X}\} \), where \( H_0(t) = \int_0^t h_0(s)ds \). Hence, (1.1) is satisfied with \( \Gamma = \beta \).

- **Accelerated failure time (AFT) regression model**: \( \log(T) = \beta^T X + \varepsilon \), where \( \varepsilon \) is the random error. Then it is easy to see that (1.1) is satisfied with \( \Gamma = \beta \).

- **Various semiparametric variants of Cox or AFT model**, for example, \( \log(T) = \beta_1^T X + g_1(\beta_2^T X) + g_2(\beta_3^T X)\varepsilon \), where \( g_2 \) is a non-negative function. The vectors \( \beta_i, i = 1, \ldots, 3 \), are unknown; and \( g_1 \) and \( g_2 \) are also possibly unknown. For this semiparametric regression model, (1.1) is satisfied with \( \Gamma \) whose columns are \( \beta_1, \beta_2 \) and \( \beta_3 \).

The purpose of this paper is twofold. First, we will estimate the central subspace \( S_{T|X} \) for high-dimensional censored data, an important problem that has not been explored much in the literature due to technical challenges. The central subspace is known to be a powerful tool for data reduction and visualization. However, it does not directly provide prediction, which is often a main objective for real data analysis. Our second goal is therefore to esti-
mate the conditional distribution function $F(T \mid X)$ in the high-dimensional setting while accounting for censoring. This would help answer important practical questions such as what is the probability that a patient can survive more than six months given his/her clinical conditions and genetic profile.

2. Related work and contribution. There exist a rich literature on central subspace estimation for dimension reduction, see Li (1991), Ye & Weiss (2003), Cook & Ni (2005), Zhu et al. (2006), Li & Wang (2007), Li (2007), Hsing & Ren (2009), Li & Dong (2009), Yin & Li (2011), Ma & Zhu (2012), Kong & Xia (2014), Chen et al. (2015), Bura et al. (2016), among many important others. More recently, progress has been made in high-dimensional setting ($p > n$) (e.g., Li & Yin 2008, Cook et al. 2012, Yu et al. 2013, Yin & Hilaefu 2015, Yu et al. 2016, Lin et al. 2018, Wang et al. 2018, Tan et al. 2018, Qian et al. 2018). However, these methods were mainly designed for complete data and do not apply to data with censored outcomes. When the response variable is censored, several authors have made significant progresses for the classical setting (fixed $p$ or $p$ diverging but $p < n$); see, e.g., Li et al. (1999), Cook (2003), Li & Li (2004), Li (2005), Xia et al. (2010), Lu & Li (2011), Nadkarni et al. (2011), Lopez (2011), Sun et al. (2018) and Zhao et al. (2017).

Our first main contribution is to significantly extend the existing theory on sufficient dimension reduction (SDR) for censored data. Based on our proposed new methodology, we establish both the central subspace estimation consistency and variable selection consistency in the ultrahigh dimensional setting without stringent parametric distributional assumptions. Furthermore, these consistency properties are achieved under relatively mild conditions on the censoring mechanism: we assume the conditional independence condition $T \perp \perp C \mid X$, as opposed to the more restrictive complete independence condition $T \perp \perp C$ or the strong marginally conditional independence condition $T \perp \perp C \mid X_j$, for all $j$, required by many screening methods.

To the best of our knowledge, our proposal is the first to extend SDR method to the analysis of high-dimensional censored data with theoretical guarantees, where $p$ is allowed to increase at an exponential rate of $n$. It is worth noting that our approach is very different from existing model-based (mostly based on Cox model) variable selection methods (e.g., Tibshirani 1997, Fan & Li 2002, Zhang & Lu 2007, Johnson 2009, Du et al. 2010, Bradic et al. 2011, Huang et al. 2013, Fang et al. 2017, Chai et al. 2018). Moreover, the proposed methods apply to a wide class of survival data models where the proportional hazards assumption is violated.

We also establish uniform convergence of a local Kaplan-Meier estima-
tor in the high dimensional setting with assistance of the estimated central subspace. The celebrated nonparametric Kaplan-Meier estimator for the conditional distribution of the event time plays a central role in survival analysis but requires the strong independent censoring assumption. On the other hand, important extensions of Kaplan-Meier estimator to covariate-dependent censoring, such as Beran (1981), only works with a few covariates in practical data analysis due to the curse of dimensionality. Our result much extends the practical use of Kaplan-Meier estimator to high-dimensional censored data while permitting covariate-dependent censoring.

In addition, we equip our method with an efficient algorithm for computation. It adopts an iterative strategy to solve the objective functions without inverting any large covariance matrix. Furthermore, we propose a specialized cross-validation method to achieve automatic tuning parameter and structural dimension selection. Its practical effectiveness is demonstrated through extensive numerical and real data evaluations.

The remainder of the paper is organized as follows. Section 3 proposes the new double-slicing assisted SDR method for studying high dimensional censored data. Section 4 establishes consistency results in both central subspace estimation and variable selection under the ultrahigh dimensional setting, as well as estimation consistency for conditional survival function. Computational aspects are presented in Section 5. Simulation studies and real data analysis are given in Sections 6 and 7, and concluding remarks are given in Section 8. Proofs, related technical details, and additional computational and numerical results are left to the Supplement.

3. Methodology. In this section, we introduce the double-slicing assisted SDR method in high dimension (abbreviated as DASH) to estimate the central subspace $S_{T|X}$ and to simultaneously select important covariates for $T|X$ in the ultrahigh dimensional settings. DASH has two main steps. First, it estimates a cruder augmented central subspace $S_{(T,C)|X}$ for the conditional distribution of $(T,C)|X$, inspired by the double slicing approach in Li et al. (1999) for the classical setting $p < n$. It then provides a refined estimate of the targeted central subspace $S_{T|X}$ adjusting for censoring in the second step. Based on the central subspace estimation from DASH, we then obtain a nonparametric estimator of the conditional survival function, which also yields an estimator for the conditional quantile function as a byproduct.

3.1. The DASH method. To motivate DASH, we provide some basic intuition for the ideal situation where we fully observe $T$ and there are only fixed number of covariates. In this case, sliced inverse regression (SIR; Li 1991) is a simple way to estimate the central subspace. Let $\mu = E(X)$ and
\[ \Sigma = \text{cov}(\mathbf{X}) \] be the mean and covariance matrix of \( \mathbf{X} \), respectively. The key observation behind SIR is that \( \mathbf{E}(\mathbf{X} - \mu \mid T) \) is in the space \( \Sigma S_{T \mid X} \) under the linearity condition in Li (1991), which holds for the elliptical distribution family and also holds to a good approximation in high dimension (Hall & Li 1993). SIR reverses the relation between the response variable and the covariates. Let \( I_t = [a_t, a_{t+1}) \), \( t = 1, \ldots, b \), be \( b \) non-overlapping intervals of a partition of the range of \( T \), where \( 0 = a_1 < \cdots < a_b < \infty = a_{b+1} \). For a given \( t \), define \( \xi_t = \Sigma^{-1}\mathbf{E}(\mathbf{X} - \mu \mid T \in I_t) \) for \( t = 1, \ldots, b \). With \( M = (\xi_1, \ldots, \xi_b) \in \mathbb{R}^{b \times p} \) and \( S_M = \text{Span}(M) \), where \( \text{Span}(M) \) is the subspace spanned by the columns of \( M \), we have \( S_M \subseteq S_{T \mid X} \). Furthermore, we assume the coverage condition \( S_M \supseteq S_{T \mid X} \), which is usually reasonable with large enough \( b \). With \( d = \text{dim}(S_M) \), the dimension of \( S_M \), Cook & Ni (2005) proposed to estimate \( S_M \) with a \( d \)-dimensional subspace that is closest to the columns of \( M \), where the closeness is measured by a quadratic discrepancy function. This general approach subsumes SIR as a special case. However, this quadratic distance approach is not applicable to our setting due to the challenges of random censoring and high-dimensional covariates.

The DASH method we introduce below corrects the bias due to random censoring by employing inverse probability weighting. Such weighting intrinsically also depends on the high-dimensional covariates. We extend the double-slicing approach of Li et al. (1999) to obtain estimates of such weights with theoretical guarantee in high dimension. Furthermore, DASH incorporates high-dimensional covariates in estimating \( S_{T \mid X} \) by extending the quadratic discrepancy function with appropriate penalization and devising an algorithm that avoids inverting the high-dimensional covariance matrix.

For censored data, \( T \) may not be completely observed. Instead of slicing \( T \), we consider \( H_y = [t_y, t_{y+1}) \), \( y = 1, \ldots, b \), which form \( b \) non-overlapping intervals of a partition of the observed survival time \( Y \) with \( 0 = t_1 < \cdots < t_b < \infty = t_{b+1} \). Let \( S(t \mid x) = P(C > t \mid \mathbf{X} = x) \) be the conditional survival function of the censoring time \( C \) given \( \mathbf{X} \). Let \( p_y = P(Y \in H_y) \) and \( \tilde{p}_y = P(T \in H_y) \). It is not hard to verify (see Supplement I.1) that

\[
E(\mathbf{X} - \mu \mid T \in H_y) = \frac{p_y}{\tilde{p}_y} \mathbf{E}\left\{ \frac{\delta(\mathbf{X} - \mu)}{S(Y \mid \mathbf{X})} \mid Y \in H_y \right\}.
\]

Hence, one can correct the censoring bias by inverse probability weighting. Variations of inverse probability weighting for censored data were also used in Fan & Gijbels (1994), Cheng et al. (1995), Lu & Li (2011), Nadkarni et al. (2011), among others, for classical fixed or small \( p \) cases. When the censoring distribution depends on the covariates, the aforementioned literature either imposed relatively strong assumptions such as complete indepen-
is the sample mean of $X$ translated by $\hat{\delta}$ the set cardinality. Then the sample estimates of $m$ modified matrix $g$ corresponding to slice $J$ called a kernel matrix. Let $t$ained. The details of estimating $\hat{S}(t | X)$ will be described in Section 3.3.

Let $m_y = E\{\delta(X - \mu)/S(Y | X) | Y \in H_y\}, y = 1, \ldots, b$. And define $M_c = (m_1, \ldots, m_b) \in \mathbb{R}^{p \times b}$. Then (3.1) implies that $S_{M_c} \subseteq \Sigma S_{T|X}$. Unless stated otherwise, we assume throughout the article that $S_{M_c} \equiv \Sigma S_{T|X}$. Let $g = (\sqrt{p_1}, \ldots, \sqrt{p_b})$ and $D_g = \text{diag}(g)$, where $\text{diag}(g)$ denotes the diagonal matrix with diagonal components to be the elements of $g$. Construct a modified matrix $U_c = M_c D_g$. Then we have $S_{U_c} = S_{M_c} = \Sigma S_{T|X}$ and $U_c$ is called a kernel matrix. Let $J_y = \{1 \leq i \leq n : Y_i \in H_y\}$ be the index set corresponding to slice $H_y$ and let $N_y = |J_y|, y = 1, \ldots, b$, where $| \cdot |$ denotes the set cardinality. Then the sample estimates of $m_y$ and $p_y$ can be formulated by $\hat{m}_y = N_y^{-1} \sum_{i \in J_y} \delta_i(X_i - X)/S(Y_i | X_i)$ and $\hat{p}_y = N_y/n$, where $X$ is the sample mean of $X$. Correspondingly, we can obtain sample estimates $\hat{M}_c$ and $\hat{g}$ of $M_c$ and $g$, and set $\hat{U}_c = \hat{M}_c D_{\hat{g}}$.

Let $\Gamma_0$ be a basis matrix of $S_{T|X}$ and let $\gamma_{0j} \in \mathbb{R}^d$ be the $j$th row of $\Gamma_0$. With $\|\cdot\|_2$ being the $L_2$ norm, let $A_0 = \{1 \leq j \leq p : \|\gamma_{0j}\|_2 > 0\}$. Then it is natural to define $X_{A_0}$ to be the active variables of $S_{T|X}$, where $X_{A_0}$ is the sub-vector of $X$ corresponding to the index set $A_0$. To achieve SDR and to simultaneously identify the active variables, we estimate $\Gamma_0$ by considering the penalized sample objective function

$$
F_n(\Gamma, \Phi) = \text{tr}\{(\hat{U}_c - \hat{\Sigma}_n \Gamma \Phi)^T \hat{\Omega}_n (\hat{U}_c - \hat{\Sigma}_n \Gamma \Phi)\} + \lambda \sum_{j=1}^p w_j \|\gamma_j\|_2,
$$

subject to $\Phi \Phi^T = I_d$, where $\text{tr}(\cdot)$ is the trace operator, $\hat{\Sigma}_n$ is the sample covariance matrix of $X$, $\hat{\Omega}_n$ denotes a sample estimate of $\Sigma^{-1}$, and $\gamma_j$ is the $j$th row vector of $\Gamma$. It is important to stress that we avoid finding an explicit form of $\hat{\Omega}_n$ by setting $\hat{\Sigma}_n \hat{\Omega}_n = I_p$ in the sample objective function in our algorithm (Section 5). In (3.2), $\lambda$ is a tuning parameter and $w_j$‘s are penalty weights. Note that each column vector in $\Gamma_0$ produces a linear combination of the $p$ covariates, and the above penalty hence encourages sparse linear combinations of all covariates.

**Remark 3.1.** We assume throughout the paper that central subspaces $S_{T|X}$ and $S_{(T,C)|X}$ exist and are unique. This assumption has been shown to hold under mild conditions (when, e.g., the covariates have density with convex support; Cook 1998, Ch. 6; Li 2018, Ch. 2.2). Then, by Proposition A.1 in the Appendix, the set of active (or relevant) variables associated with the
Remark 3.2. The loss function in (3.2) is motivated by the quadratic discrepancy approach discussed in Cook & Ni (2005) as we can rewrite the population version of the loss function as

\[(3.3) \quad F(\Gamma, \Phi) = (\text{vec}(\tilde{U}_c) - \text{vec}(\Gamma\Phi))^T W (\text{vec}(\tilde{U}_c) - \text{vec}(\Gamma\Phi)),\]

where vec(·) denotes the operator that constructs a vector from a matrix by stacking its columns, \(\otimes\) denotes Kronecker product, \(\tilde{U}_c = \Sigma^{-1}U_c\) satisfies \(S_{\tilde{U}_c} \equiv S_{T|X}\), and \(W = I_p \otimes \Sigma\) is positive-definite. See also Proposition A.2 in the Appendix for the motivation. In the population version, (A.1) does not involve \(\Sigma^{-1}\) after expansion, and we thus avoid inverting a large covariance matrix in high dimension. For identifiability, instead of imposing constraints on basis \(\Gamma\) like many SDR methods, we use an alternative constraint \(\Phi \Phi^T = I_d\) to overcome computational challenges in the ultrahigh dimensional setting. As discussed in Section 5, the new constraint will lead to iterative optimization steps that involves singular value decomposition (SVD) of relatively small matrix, which is efficient to compute.

Remark 3.3. Here, we take \(\hat{\Sigma}_n\) to be the sample covariance matrix of \(X\). Alternatively, we can use other estimators such as a thresholded covariance matrix (Bickel & Levina 2008). Unless stated otherwise, we simply assume sample covariance is used, but we also use the thresholded covariance for numerical studies in Section 6.

Remark 3.4. The derivation of the penalty weights \(w_j\) follows a variant of the adaptive group lasso (Zou 2006, Yuan & Lin 2006): we first obtain an initial estimator \((\hat{\Gamma}_0, \hat{\Phi}_0)\) of (3.2) by using equal weights \(w_1 = \cdots = w_p = 1\) with tuning parameter \(\hat{\lambda}\); then we set weights by \(w_j = ||\hat{\gamma}_{0j}||_2^\rho\) to find the estimator \((\hat{\Gamma}_0, \hat{\Phi}_0)\), where \(\hat{\gamma}_{0j}\) is the \(j\)th row of \(\hat{\Gamma}_0\) and \(\rho\) is some pre-specified constant. We can also define \(w_j = +\infty\) if \(||\hat{\gamma}_{0j}||_2 = 0\). The estimator for \(S_{T|X}\) is then \(\hat{S}_{\Gamma_0}\), and the estimated set of active variables is \(\hat{A}_0 = \{1 \leq j \leq p : ||\hat{\gamma}_{0j}||_2 > 0\}\), where \(\hat{\Gamma}_0 = (\hat{\gamma}_{01}, \cdots, \hat{\gamma}_{0p})^T\). The detailed computational algorithm and tuning parameter selection related to (3.2) are presented in Section 5.

3.2. Nonparametric estimation of conditional survival function. We now describe how we can construct a nonparametric estimator of the conditional survival function \(Q(T|X)\) based on the central subspace obtained in Section 3.1. Estimating the conditional survival function is often of independent interest.

The estimated central subspace allows us to estimate \(Q(t|x) = P(T > t|\Gamma_0^T X = \Gamma_0^T x)\) as \(\Gamma_0\) is a basis matrix of \(S_{T|X}\). The dimension of \(\Gamma_0^T X\)
is usually low and we assume it is upper bounded. In addition, as shown in Proposition A.3 in the Appendix, conditioning on $\Gamma_0^T X$, the conditional independence assumption remains to hold. We generalize the local Kaplan-Meier (KM) estimator (e.g., Beran 1981, Gonzalez-Manteiga & Cadarso-Suarez 1994, Zeng 2004) to estimate $Q(t \mid x)$ by

$$
\hat{Q}(t \mid x) = \prod_{i=1}^{n} \left\{ 1 - \frac{I(Y_i \leq t, \delta_i = 1)B_{ni}(\hat{\Gamma}_0^T x)}{\sum_{k=1}^{n} I(Y_k \geq Y_i)B_{nk}(\hat{\Gamma}_0^T x)} \right\},
$$

where $B_{ni}(\hat{\Gamma}_0^T x)$ are nonparametric local weights, and $\hat{\Gamma}_0$ is the estimator for $\Gamma_0$ obtained in Section 3.1 with transformation to be an semi-orthogonal matrix (e.g., we can simply perform a SVD on $\hat{\Gamma}_0 \hat{\Phi}_0$ to obtain this matrix; this step is only for convenience of technical analysis and, as shown in Proposition A.4 in Appendix, ensures the existence of a basis $\Gamma_0 \in S_{T \mid X}$ that is close enough to the transformed estimator). Two popular choices of weights are the histogram weight and the Nadaraya-Watson weight. To use the histogram weight, we partition the support $Z \subset \mathbb{R}^d$ of $\hat{\Gamma}_0^T X$ into small sub-domains; given $z \in Z$, let $\mathcal{M}(z)$ be the sub-domain containing $z$ and let $N_n(z)$ be the number of observations $Z_i = \hat{\Gamma}_0^T X_i$ $(1 \leq i \leq n)$ that are contained in $\mathcal{M}(z)$. Then $B_{ni}(z) = 1/N_n(z)$ if $\mathcal{M}(z) = \mathcal{M}(Z_i)$, and $B_{ni}(z) = 0$ otherwise. To use the Nadaraya-Watson weight, we set $B_{ni}(z) = K(Z_i - z)h_n / \sum_{k=1}^{n} K(Z_k - z)h_n$, where $K(\cdot)$ is a kernel function and $h_n$ is the bandwidth. In Section 4, we establish the uniform convergence for the local KM estimator in (3.4). The proposed estimator much broadens the practical use of Kaplan-Meier estimator in high dimension.

As one interesting and useful application of the estimated survival function $\hat{Q}(t \mid X)$, we can further estimate the conditional quantile function for $T \mid X$. That is, given $0 < \tau < 1$, we directly estimate the $\tau$th conditional quantile by inverting $\hat{Q}(t \mid X)$. In Section 4, we show that this produces a consistent estimator for $Q_T(\tau \mid X) = \sup\{ t : Q(t \mid X) < 1 - \tau \}$. See also the numerical illustration in Section 6.

### 3.3. Double-slicing assisted preliminary estimator of $S(t \mid X)$ in high dimension.

In Section 3.1, we discussed the need to flexibly estimate $S(t \mid X)$ for inverse probability weighting in (3.1). In this subsection, we provide the details on how such a preliminary estimator can be obtained in high dimension by extending the seminal work of Li et al. (1999), which was developed for the small $p$ large $n$ setting. The basic idea is to consider a slightly larger subspace based on the sufficient reduction for $(T, C) \mid X$, which also provides a sufficient reduction for $C \mid X$ and can facilitate the estimation of $S(t \mid X)$. Therefore, we first reduce the dimension of $X$ through the augmented central subspace $\hat{S}_{(T, C) \mid X}$ and then estimate $S(t \mid X)$ nonparametrically based...
on the dimension reduced predictors.

Specifically, because \((Y, \delta)\) is a function of \((T, C)\), we have that \(S_{(Y,\delta)X} \subseteq S_{(T,C)X}\) (e.g., Theorem 2.3, Li 2018). In addition, Proposition A.5 in the Appendix shows that the coverage condition \(S_{(Y,\delta)X} \supseteq S_{(T,C)X}\) is equivalent to \(S_{T|X} \subseteq S_{(Y,\delta)X}\) and \(S_{C|X} \subseteq S_{(Y,\delta)X}\); the latter conditions are often reasonable considering that \(S_{Y|X} \subseteq S_{(Y,\delta)X}\) and \(P(Y > t | X) = P(T > t | \Gamma_0X)P(C > t | \Gamma_0X, X)\) from the conditional independence, where \(\Gamma_0\) and \(\Gamma_c\) are basis of \(S_{T|X}\) and \(S_{C|X}\), respectively. Then assuming a full coverage, \(S_{(T,C)X}\) can be estimated through \(S_{(Y,\delta)X}\) by the sliced inverse regression method with double slicing on \(Y\) and \(\delta\). This idea eases the central subspace estimation as both \(Y\) and \(\delta\) are observable.

Let \(\mathcal{H}_{1,l}, l = 1, \ldots, b_1\), be the \(b_1\) non-overlapping intervals of the discretized event time \(Y\) without censoring \((\delta = 1)\), and let \(\mathcal{H}_{0,l}, l = 1, \ldots, b_0\), be \(b_0\) non-overlapping intervals of the discretized \(Y\) with censoring \((\delta = 0)\). With the double-slicing (DS) practice, similar to our discussion for (3.1), it can be shown that

\[
m_{k,l} := \mathbf{E}(X | Y \in \mathcal{H}_{k,l}, \delta = k) - \mu \in \Sigma S_{(T,C)X}
\]

for any \(k = 0, 1\), and \(l = 1, \ldots, b_k\), under the linearity condition. Define \(M_1 = (m_{1,1}, \ldots, m_{1,b_1}, m_{0,1}, \ldots, m_{0,b_0}) \in \mathbb{R}^{p\times(b_1+b_0)}\), \(p_{k,l} = P(Y \in \mathcal{H}_{k,l}, \delta = k)\), and \(g_1 = (\sqrt{p_{1,1}}, \ldots, \sqrt{p_{1,b_1}}, \sqrt{p_{0,1}}, \ldots, \sqrt{p_{0,b_0}})\). By setting \(U_1 = M_1D_{g_1}\), we have \(S_{U_1} = M_1 = \Sigma S_{(T,C)X}\). Then \(U_1\) is a kernel matrix for \(S_{(T,C)X}\). Let \(d_1 = \text{dim}(S_{(T,C)X})\). By replacing \(U_c\) with \(U_1\) in (3.1), we have the objective function

(3.5) \(F_1(\Gamma, \Phi) = \text{tr} \{ (U_1 - \Sigma \Gamma \Phi)^T \Sigma^{-1} (U_1 - \Sigma \Gamma \Phi) \}\), subject to \(\Phi \Phi^T = I_{d_1}\),

where \(\Gamma \in \mathbb{R}^{p\times d_1}\) and \(\Phi \in \mathbb{R}^{d_1\times(b_1+b_0)}\) are parameters, and its minimizer \(\Gamma_1 \in \mathbb{R}^{p\times d_1}\) of \(\Gamma\) forms a basis of \(S_{(T,C)X}\). Likewise, with \(\hat{U}_1 = \Sigma^{-1}U_1\), this objective function also forms a quadratic discrepancy function resembling (3.3).

Define \(J_{k,l} := \{ 1 \leq i \leq n : Y_i \in \mathcal{H}_{k,l} \text{ and } \delta = k \}\) to be the index set corresponding to slice \(\mathcal{H}_{k,l}\), and \(N_{k,l} = |J_{k,l}|\). Let \(\hat{M}_{k,l} = X_{k,l} - X = \sum_{i \in J_{k,l}} X_i/N_{k,l} - X\) and \(\hat{p}_{k,l} = N_{k,l}/n\), which are used to construct the sample estimators \(\hat{M}_1\) and \(\hat{g}_1\) for \(M_1\) and \(g_1\). Set \(\hat{U}_1 = \hat{M}_1D_{\hat{g}_1}\). Under sparsity, let \(A_1\) be the index set corresponding to active variables of \(S_{(T,C)X}\). Assume \(q_1 := |A_1| < p\). We can then use \(\hat{U}_1\) to formulate a penalized sample objective function similar to (3.2) to estimate \(S_{(T,C)X}\) and \(A_1\) by minimizing

(3.6) \(F_1n(\Gamma, \Phi) = \text{tr} \{ (\hat{U}_1 - \hat{\Sigma}_n \Gamma \Phi)^T \hat{\Sigma}_n (\hat{U}_1 - \hat{\Sigma}_n \Gamma \Phi) \} + \lambda \sum_{j=1}^{p} w_j \| \gamma_j \|_2\),

subject to \(\Phi \Phi^T = I_{d_1}\), where \(\lambda\) is tuning parameter with unequal penalty.
weights. Here we perform the same adaptive estimation procedure as described for (3.2), and set \( \hat{\lambda}_1 \) to be the tuning parameter corresponding to the initial equal penalty weights. With the estimator \((\hat{\Gamma}_1, \hat{\Phi}_1)\) from (3.6), this DS procedure generates the estimated central subspace \( \mathcal{S}_{\hat{\Gamma}_1} \) and variable selection set \( \hat{A}_1 = \{1 \leq j \leq p : \|\hat{\gamma}_{1j}\|_2 > 0\} \), where \( \hat{\Gamma}_1 = (\hat{\gamma}_{11}, \ldots, \hat{\gamma}_{1p})^T \).

Since \( \Gamma_1^T X \) is a sufficient reduction for \( C \mid X \), we have \( S(t \mid x) = P(C > t \mid \Gamma_1^T X = \Gamma_1^T x) \). Similar to (3.4), we assume \( d_1 \) is upper bounded. Thus, with the help of low-dimensional estimator \( \hat{\Gamma}_1 \), the local KM estimation is applied to estimate \( S(t \mid x) \) as

\[
\hat{S}(t \mid x) = \prod_{i=1}^{n} \left\{ 1 - \frac{I(Y_i \leq t, \delta_i = 0)B_{ni}(\Gamma_1^T x)}{\sum_{k=1}^{n} I(Y_k \geq Y_i)B_{nk}(\Gamma_1^T x)} \right\},
\]

where \( B_{ni}(\cdot) \)'s are the weight functions as described for (3.4).

**Remark 3.5.** Since the sufficient reduction for \( (T, C) \mid X \) is also a sufficient reduction for \( T \mid X \), the proposed DS method not only achieves dimension reduction to facilitate the estimation of \( S(t \mid X) \), but also provides reduction for the targeted \( T \mid X \). However, as \( S_{(T,C)\mid X} \) is usually a larger space than \( S_{T\mid X} \), it might still contain redundant information for the ultimate reduction of \( T \mid X \). Nevertheless, the DS method can be efficiently adapted to our high dimensional framework, and is worthy as an initial assisting step for reduction. Since \( S_{T\mid X} \subseteq S_{(T,C)\mid X} \), we have \( A_0 \subseteq A_1 \) and \( q_1 \geq q \). When \( S_{(T,C)\mid X} = S_{T\mid X} \), \( A_1 = A_0 \), and the DS method itself achieves simultaneous SDR and variable selection for \( S_{T\mid X} \). In Section 6, we will evaluate and compare the DS estimator with the DASH estimator under different simulation scenarios.

4. **Theoretical results.** In this section, we state the main theoretical results of the proposed methods in ultrahigh dimension that allows \( p \) to grow exponentially with \( n \). Under this setting, we first establish consistency properties for the DS method targeting \( S_{(T,C)\mid X} \). With these results as preparation, we then investigate consistency properties for DASH targeting \( S_{T\mid X} \) and the subsequently estimated conditional survival function \( \hat{Q}(t \mid x) \) with local KM estimator.

4.1. **DS estimator.** Let \( \mu_j = \text{E}(X_j) \), \( \mu_{yj} = \text{E}(X_j \mid Y \in \mathcal{H}_y) \) and \( \mu_{k,l,j} = \text{E}(X_j \mid Y \in \mathcal{H}_{k,l}, \delta = k) \) for \( 1 \leq j \leq p, 1 \leq y \leq b, k = 0, 1 \) and \( 1 \leq l \leq b_k \). Define \( \bar{b} = \max(b_1, b_0) \) and \( \sigma_{ij} = (\Sigma)_{ij} \). Let \( \lambda_{\text{min}}(\cdot) \) denote the minimum eigenvalues of a square matrix. Let \( e_j \) be the vector with the \( i \)th element to be one and the rest to be zeros. Consider the following regularity conditions.
(A1) Let $G$ be a basis matrix of $S = S_{(T,C)}|X$ or $S_{T}X$. Assume $X$ satisfies $E(X - \mu | G^T X) = AG^T(X - \mu)$ for some matrix $A \in \mathbb{R}^{p \times \text{dim}(S)}$.

(A2) There is a positive constant $c_H$ such that $P(Y \in H_{k,l}, \delta = k) \geq c_Hb^{-1}$ for all $k = 0, 1$ and $1 \leq l \leq b_k$.

(A3) For all $\epsilon > 0$, there is a constant $c_1 > 0$ such that for all $1 \leq j \leq p$, $P(|X_j - \mu_j| > \epsilon) \leq 2 \exp(-c_1 \epsilon^2)$. In addition, for all $\epsilon > 0$, $1 \leq j \leq p$, $1 \leq y \leq b$, $k = 0, 1$ and $1 \leq l \leq b_k$, there are constants $c_2, \tilde{c}_2 > 0$ such that $P(|X_j - \mu_{yj}| > \epsilon | Y \in H_{yj}) \leq \tilde{c}_2 \exp(-c_2 \epsilon^2)$ and $P(|X_j - \mu_{k,l,j}| > \epsilon | Y \in H_{k,l}, \delta = k) \leq \tilde{c}_2 \exp(-c_2 \epsilon^2)$.

(A4) Assume that $\sigma_{ij} < \tilde{\sigma}$ $(1 \leq i, j \leq p)$ and $\lambda_{\min}(\Sigma) > \sigma_*$, where $\sigma_{ij}$ is the $(i,j)$-element of $\Sigma$, and $\sigma_*$ and $\tilde{\sigma}$ are some positive constants.

(A5) Assume the nonzero singular values of $\hat{U}_1$ are bounded away from zero.

(A6) Assume $\min_{j \in A_1} \| U_1 U_1^T e_j \|^p > c_u n^{-\tau_1}$ for some $0 \leq \tau_1 < 1$.

Condition (A1) is the linearity condition discussed in Section 3. Condition (A2) assumes that all slices of the response have reasonably large marginal probability, which is mild and is often satisfied in practice. The first component in (A3) is the commonly used uniformly sub-Gaussian assumption for the marginal distribution of predictors $X_j$ $(1 \leq j \leq p)$. The second component in (A3) further assumes uniformly sub-Gaussian condition for $X_j$ given each slice; if $b$ and $\tilde{b}$ are upper bounded, these two components are essentially equivalent. Condition (A4) assumes that all elements in $\Sigma$ are uniformly upper bounded with minimum eigenvalue bounded from zero. Conditions (A5) and (A6) includes mild assumptions on the “kernel” matrix $\hat{U}_1$: (A5) holds if the nonzero eigenvalues of $\text{Var}(E(X | \hat{Y}))$ are bounded away from zero, where $\hat{Y}$ is the double-sliced response; (A6) uses a marginal utility quantity condition (Zhu et al. 2012) to control signal levels. To obtain consistency results, define $P_S$ to be the projection matrix onto a given subspace $S$, and let $\| \cdot \|_F$ be the Frobenius norm. Define $\hat{p}_n = \max(p,n)$. The following condition allows $p$ to grow exponentially with $n$.

(A7) Assume $\bar{b}^2 q_1 \log \hat{p} = O(n^{1-\zeta_1})$ and $q_1^2 \log \hat{p}_n = O(n^{1-\zeta_1})$ for some constant $\zeta_1$ with $\tau_1 < \zeta_1 < 1$.

**Theorem 4.1.** Assume Conditions (A1)–(A7) hold. Suppose that $\hat{\lambda}_1 = 2c_{1n} \sqrt{\log \hat{p}_n/n}$, $\lambda_1 = 2^{-\rho} c_{u1}^{\rho/2} c_{1n} \sqrt{\log \hat{p}_n/n}^{1+\rho \tau_1}$ and $\rho(\zeta_1 - \tau_1) \geq 1 - \zeta_1$, where $c_{1n} = (C_1 \bar{b} + C_2 q_1^{1/2})/2$ with $C_1, C_2$ being some generic positive constants (given in Theorem 1.2 of Supplement I.4). Then the DS estimator of
Section 3.3 satisfies
\begin{align}
(4.1) \quad & \|P_{S_{T,1}} - P_{S(T,C)|X}\|_F = O_p\left((\hat{b} + q_1^{1/2})\sqrt{q_1 \log \tilde{p}_n/n}\right), \\
(4.2) \quad & P(\hat{A}_1 = A_1) \to 1 \text{ as } n \to \infty.
\end{align}

Theorem 4.1 shows that the estimation consistency and the variable selection consistency of $S_{(T,C)|X}$ can be simultaneously established by our DS method without imposing stringent conditions. In addition to $p$, the theorem allows $q_1$ and $\hat{b}$ to diverge with $n$. If $\hat{b}$ is upper bounded, the convergence rate of the central subspace estimation is $O_p\left(q_1 \sqrt{\log \tilde{p}_n/n}\right)$; if $q_1$ is upper bounded, it is $O_p\left(\hat{b} \log \tilde{p}_n/n\right)$; with both $q_1$ and $\hat{b}$ upper bounded, the result is simplified to $O_p\left(\sqrt{\log \tilde{p}_n/n}\right)$.

4.2. DASH estimator. The results in Theorem 4.1 target on $S_{(T,C)|X}$, which can be a larger subspace than our main interest $S_{T|X}$. We next establish theoretical properties for the DASH method targeting $S_{T|X}$. Unless stated otherwise, assume that the Nadaraya-Watson kernel-based KM estimator is applied to obtain $\hat{S}(t | X)$. For technical brevity, we assume uniform kernel function $\hat{K}(x) = I(\|x\|_2 \leq 1)$ is used, although other popular kernel choices can apply. Assume data splitting (Cox 1975) is applied so that $\hat{\Gamma}_1$ and the local KM estimation use different data halves, and $\hat{S}(t | X_i)$ is obtained via the leave-one-out technique (Härdle et al. 1993), where the product in (3.7) omits the $i$th sample point. Suppose the domain $\mathcal{X}$ of $X$ is compact with $\|X\|_2 \leq K$ for some constant $K > 0$. Consider the following regularity conditions.

(C1) Suppose $P(T \geq C \geq t | X) \geq \tau_0$ for any $t \in [0,T_0]$ and $X \in \mathcal{X}$, where $\tau_0$ is some positive constant and $T_0$ is the maximum follow-up time.

(C2) Given a basis $\Gamma_1 \in S_{(T,C)|X}$, $m(t | z) := P(T > t | \Gamma_1^T X = z)$ and $\hat{m}(t | z) := P(C > t | \Gamma_1^T X = z)$, assume that $|m(t | z_1) - m(t | z_2)| \leq c_1\|z_1 - z_2\|_2$ and $|\hat{m}(t | z_1) - \hat{m}(t | z_2)| \leq \hat{c}_1\|z_1 - z_2\|_2$ hold for any $t \in [0,T_0]$, where $c_1$ and $\hat{c}_1$ are some positive constants.

(C3) Given a basis $\hat{\Gamma}$ of $S_{(T,C)|X}$ or $S_{T|X}$, the density of $\Gamma^T X$ is positive and bounded from zero on $\mathcal{Z}$, where $\mathcal{Z} = \{\Gamma^T X : X \in \mathcal{X}\}$. In addition, the density of $\Gamma^T X$ satisfies Lipschitz condition for $\Gamma$ on a neighborhood of $\hat{\Gamma}$ in $\|\cdot\|_F$-norm.

(C4) For every $1 \leq y \leq b$, there exists a constant $c_s > 0$ such that $P(Y \in \mathcal{H}_y) \geq c_s b^{-1}$.

(C5) Assume $\min_{j \in \mathcal{A}_0} e_j^T \hat{U}_c \hat{U}_c^T e_j > c_{a_2} n^{-\tau_2}$ for some $0 \leq \tau_2 < 1$. The nonzero singular values of $\hat{U}_c$ are bounded away from zero.
Compared to the consistency result (4.1) of the initial DS estimator, the DASH method achieves estimation consistency for $S$ and selection consistency. From (4.3), when $b, b_1$ and $q_1$ are all upper bounded, the DASH estimator converges at the rate of $O_p((\log \tilde{p}_n/n)^{1/2})$. The somewhat slower convergence rate relative to (4.1) is mainly due to the key inverse probability weighting procedure, but this enables us to target the true central subspace $S_{\mathcal{T}|X}$, instead of the larger $S_{(T,C)|X}$. Interestingly, under classical fixed $p$ scenarios, if $d \geq d_1/2$ (that is, $\dim(S_{\mathcal{T}|X})$ is allowed to be as small as half of $\dim(S_{(T,C)|X})$, the rate for DASH matches (up to a logarithmic factor) or exceeds the known convergence rate $O_p(n^{-\frac{1}{2(1+\rho)}})$ in Nadkarni et al. (2011).

Remark 4.1. In the discussion above, we assume that $S_{(T,C)|X}$ is truly sparse in the sense that the number of active variables (that is, $|A_0|$) is much smaller than $p$. Interestingly, our results can be extended to a weaker condition to allow an “approximately” sparse scenario where a large number
of variables are active for $S_{(T,C)}|X$. Specifically, recall that $\Gamma_1$ denotes a basis of $S_{(T,C)}|X$ that gives a minimizer of (3.5). Given any index set $\mathcal{A} \subset \{1, \ldots, p\}$, let $\Gamma_{1,\mathcal{A}}$ be the $|\mathcal{A}| \times d_1$ matrix consisting of the rows of $\Gamma_1$ corresponding to $\mathcal{A}$. Then rather than requiring that only a small subset of variables are active, we assume that there exists an index set $\tilde{\mathcal{A}}_1 \subset \{1, \ldots, p\}$ with $q_1 = |\tilde{\mathcal{A}}_1| < p$ and a (small) parameter $\theta > 0$ such that

$$\|\Gamma_{1,\tilde{\mathcal{A}}_1}\|_{2,1} \leq \theta,$$

where $\|\cdot\|_{2,1}$ is the $l_{2,1}$ norm (that is, $\|\Gamma_{1,\tilde{\mathcal{A}}_1}\|_{2,1} = \sum_{j \in \tilde{\mathcal{A}}_1} \|\gamma_{1j}\|_2$ and $\gamma_{1j}$ is the $j$th row of $\Gamma_1$). By Proposition A.6 in the Appendix, given the objective (3.5), the assumption of (4.5) is well-defined as $\|\Gamma_{1,\mathcal{A}}\|_{2,1}$ is unique.

Under the weaker condition of (4.5), on the one hand, $S_{(T,C)}|X$ is not strictly sparse according to the definition of active variables in Section 3; on the other hand, as the magnitude of $\Gamma_1$ in $\tilde{\mathcal{A}}_1$ is relatively small, it is still possible to approximate the (non-sparse) $S_{(T,C)}|X$ by a sparse model. Therefore, the extended setting here, to some extent, shares the flavor of both the abundant variable settings in SDR (e.g., Cook et al. 2012) and the approximately sparse conditions in linear models (e.g., Zhang & Huang 2008). With the weaker form of sparsity, we have the following theorem.

**Theorem 4.3.** Assume Conditions (A1)–(A5) and (A7) hold. Suppose that $\theta = o(1)$ and $\lambda_1 = 3c_1n \sqrt{\log p/n}$ with equal weights $w_j = 1$ for $1 \leq j \leq p$, where $c_1n$ is defined as in Theorem 4.1. Then the DS estimator satisfies

$$\|P_{S_{t_1}} - P_{S_{(T,C)}|X}\|_F = O_p\left(\max\left\{\tilde{b}^{1/2}, \sqrt{q_1 \log p/n} \right\}\right).$$

In addition, suppose that $\theta = O(\tilde{b}^{1/2} \sqrt{q_1 \log p/n})$ and $\theta = O(q_1 \sqrt{\log p/n})$ and further assume that the additional conditions of Theorem 4.2 hold. Then the DASH estimator satisfies the consistency properties of (4.3) and (4.4).

In particular, if $\theta = 0$, (4.5) reduces back to the strict sparsity conditions for $S_{(T,C)}|X$ in Section 3.3, and the convergence result of (4.6) becomes the same as (4.1) in Theorem 4.1. If $\theta$ is positive but converges to 0, by approximating $S_{(T,C)}|X$ with a parsimonious model from the DS method, we also note that the final DASH estimator may still be consistent for estimation of $S_{T}|X$, at some possible cost of the convergence rate.

4.3. Local KM estimator. As discussed in Section 3.2, with $\hat{\Gamma}_0$ available, we can subsequently apply popular nonparametric estimation methods to estimate $Q(t \mid x)$. In the following, suppose the local KM estimator (3.4) with Nadaraya-Watson kernel weighting scheme is applied. Similar to $\hat{S}(t \mid x)$, we assume same techniques with uniform kernel are used, but we
can generalize the results to other kernel function choices. The following theorem provides a uniform estimation consistency result for $Q(t \mid x)$.

**Theorem 4.4.** Suppose the conditions of Theorem 4.2 are satisfied. Then given any $x_0 \in X$, the local KM estimator satisfies
\[
\sup_{t \in [0, T_0)} |\hat{Q}(t \mid x_0) - Q(t \mid x_0)| = O_p\left(\left(bq^{1/2}\frac{\log \bar{p}_n}{n}\right)^{1/(1+d_1)} + \left(bq_1^{1/2} + q_1 + b^{1/2}\right)\left(bq_{\log \bar{p}_n}\right)^{1/2}\right).
\]

(4.7)

By employing the Nadaraya-Watson based local KM estimator, the consistency rate upper bound obtained in Theorem 4.4 is the same as that of (4.3). Likewise, when $b$, $\bar{b}$ and $q_1$ are all upper bounded, the local KM estimator can converge at the rate of $O_p((\log \bar{p}_n/n)^{1/2+d_1})$. It is worth noting that other nonparametric methods may also be applied to estimate $Q(t \mid x)$. For example, histogram-based local KM method may be used and we can provide a similar uniform estimation error bound for $Q(t \mid x)$, which is left in Supplement I.5.

**Corollary 4.1.** Suppose the conditions of Theorem 4.2 are satisfied. Then given any $x_0 \in X$ and $0 < \tau < 1$, the $\tau$th conditional quantile estimator $\hat{Q}_T(\tau \mid x_0) = \sup\{t : \hat{Q}(t \mid x_0) < 1 - \tau\}$ is a consistent estimator for $Q_T(\tau \mid x_0)$.

With the estimated survival function, we naturally obtain a consistent estimator for conditional quantiles of the survival time as described in Corollary 4.1. Beyond all these consistency results, post selection inference on SDR (with censored data) may need to directly involve the set of selected variables besides central subspace estimation error; it is an interesting yet challenging problem in its own right, which is left for future studies.

5. Computation. As we described in Section 3, the algorithm for the DASH method involves a DS estimation step followed by an IPCW based step. We summarize the procedures for DASH in Algorithm 1.

It remains to consider two practically important issues: 1) how to find proper values for tuning parameters and structural dimensions ($d_1, \lambda_1, \lambda_1$), $h_n$ and $(d, \lambda, \lambda)$; 2) how to solve optimization problems for the objective functions (3.2) in Step 2(c) and (3.6) in Step 1(b). Accordingly, we propose the procedures of tuning parameters and structural dimension determination in Section 5.1. Section 5.2 explains the algorithm used to solve (3.2), which is also applicable to solving Step 1(b).
Algorithm 1 DASH method for censored data.

1. An initial DS estimation step
   (a) Construct the kernel matrix $\hat{U}_{1}$ and covariance estimation $\hat{\Sigma}_{n}$.
   (b) Given $d_1, \tilde{\lambda}_1$ and $\lambda_1$, find minimizer $(\hat{\Gamma}_1, \hat{\Phi}_1)$ of (3.6).

2. An IPCW-based estimation step
   (a) Given $h_n$, apply the local KM estimation method with the DS estimator to find $\hat{S}(t|X_i)$ by (3.7).
   (b) Construct the kernel matrix $\hat{U}_{c}$.
   (c) Given $d, \tilde{\lambda}$ and $\lambda$, find minimizer $(\hat{\Gamma}_0, \hat{\Phi}_0)$ of (3.2).

3. Apply a nonparametric method discussed in Section 3.2 to estimate $Q(t|X)$.

5.1. Tuning parameter and structural dimension selection. We propose to use cross-validation (CV) procedures to determine $(d_1, \tilde{\lambda}_1, \lambda_1)$, $h_n$ and similarly $(d, \tilde{\lambda}, \lambda)$ in their respective steps. As discussed in Yang (2007), CV is often considered as a natural approach for complicated nonparametric procedure/model comparison purposes. As will be seen, the main challenge of applying CV is that the true survival time is not always observable. We propose a new sequential data-driven approach that integrates inverse weighting ideas for prediction error measurements (Gerds & Schumacher 2007) into the parameter/dimension determination. Since $(d_1, \tilde{\lambda}_1, \lambda_1)$ can be chosen by procedures similar to that of $(d, \tilde{\lambda}, \lambda)$, for brevity, we next assume $(d_1, \tilde{\lambda}_1, \lambda_1)$ has been chosen, and only describe in detail how to find $h_n$ and $(d, \tilde{\lambda}, \lambda)$ sequentially.

5.1.1. Determining $h_n$. We intend to find $h_n$ used in Step 2(a). Given a specified time point $\tau_m$ (e.g., $\tau_m = \text{median}(Y_i)$), define $\delta^* = I(C > \tau_m)$. For each candidate $h_n$, we estimate $E(\delta^* | X) = S(\tau_m | X)$ by the local KM estimation using the estimation set $Z_{(-k)}$, and denote this estimator by $\hat{S}_{(-k)}(\tau_m | X, h_n)$. Then we define the prediction mean square error $\text{MSE}(h_n) := E[\delta^* - \hat{S}_{(-k)}(\tau_m | X, h_n)]^2$. With the censored data, $\delta^*$ is not always observed. As a solution, $\text{MSE}(h_n)$ can be equivalently written as $E[\delta^* - \hat{S}_{(-k)}(\tau_m | X, h_n)]^2 W$, where $W = \frac{I(Y > \tau_m)}{Q(\tau_m | X)} + \frac{I(Y \leq \tau_m)(1-\delta)}{Q(Y | X)}$ is a weighting variable. Consequently, given a set $\mathcal{G}$ of candidates $h_n$’s, we can now
determine the parameter \( h_n = h_{\text{opt}} \) by
\[
(5.1)
\]
\[
\hat{h}_{\text{opt}} := \arg \min_{h \in \mathcal{G}} \hat{\text{MSE}}(h) = \arg \min_{h \in \mathcal{G}} \frac{1}{n} \sum_{k=1}^{K} \sum_{i \in I_k} \hat{W}_i \left( \delta_i^* - \hat{S}_{(k)}(\tau_m | X_i, h) \right)^2,
\]
where \( \hat{W}_i = \frac{I(Y_i > \tau_m)}{Q(\tau_m | X_i)} + \frac{I(Y_i \leq \tau_m)(1 - \delta_i)}{\hat{Q}(Y_i | X_i)} \) and \( \hat{Q}(t | X) \) is a local KM estimation of \( Q(t | X) \) using the reduction \( \hat{\Gamma}_I^T X \). Since our computation is all based on dimension reduced predictors, selection for \( h_n \) is computationally fast.

5.1.2. Determining \((d, \hat{\lambda}, \lambda)\). In Step 2(c), to find \((d, \hat{\lambda}, \lambda)\), we again apply specialized sequential CV and the aforementioned weighting techniques to naturally handle performance evaluation. Specifically, we perform the following steps.

(i) Given a candidate \( d \) and a sequence of candidate \( \hat{\lambda} \)'s, using data \( Z_{(-k)} \) \((k = 1, \ldots, K)\) with \( w_j = 1 \) \((j = 1, \ldots, p)\), compute the solution path of (3.2) and denote the estimators by \((\hat{\Gamma}_{(-k)}, \hat{\Phi}_{(-k)})\).

(ii) With \( Z_{(-k)} \) and \( \hat{\Gamma}_{(-k)} \), compute the local KM estimator \( \hat{Q}_{(-k)}^*(t | X) \) for \( Q(t | X) \) based on the reduction \( \hat{\Gamma}_{(-k)}^T X \). The bandwidth for \( \hat{Q}_{(-k)}^*(t | X) \) is automatically determined by a CV within \( Z_{(-k)} \) using similar procedures as in Section 5.1.1 by switching the roles of \( T \) and \( C \).

(iii) With each candidate \((d, \hat{\lambda})\) and their corresponding \( \hat{Q}_{(-k)}^* \)'s, evaluate the out-of-sample prediction performance by computing
\[
(5.2) \quad \hat{\text{MSE}}_2(d, \hat{\lambda}) := \frac{1}{n} \sum_{k=1}^{K} \sum_{i \in I_k} \hat{W}_i^* \left( \delta_i^* - \hat{Q}_{(-k)}^*(\tau_m | X_i) \right)^2,
\]
where \( \delta_i^* = I(T > \tau_m) \) and \( \hat{W}_i^* = \frac{I(Y_i > \tau_m)}{S(\tau_m | X_i)} + \frac{I(Y_i \leq \tau_m)\delta_i}{S(Y_i | X_i)} \).

(iv) With \((d, \hat{\lambda})\) chosen by minimal (5.2), compute (3.2) with the whole data to find \( \hat{\Gamma}_0 \). Then set \( w_j = \| \hat{\gamma}_0 \|_2^2 \) and repeat Steps (i)-(iv) with the previously selected \( d \) to determine \( \lambda \).

The determination of \((d_1, \hat{\lambda}_1, \lambda_1)\) is obtained similarly. But the detailed procedures are slightly different and simpler because DS does not involve the delicate survival function estimation issues. Accordingly, in Step (ii), rather than using the local KM estimator, we apply the tree classification (Breiman et al. 1984) with pruning to predict the response slice; in Step (iii), rather than using \( \hat{\text{MSE}}_2(d, \hat{\lambda}) \), we compute slice classification errors to evaluate prediction performance.

Since \((d_1, \hat{\lambda}_1, \lambda_1)\), \( h_n \) and \((d, \hat{\lambda}, \lambda)\) are determined sequentially instead of combinatorially and nonparametric estimation method like local KM estima-
tion and tree classifications are all performed on dimension reduced covariates, these important tuning parameters are thus automatically determined in our algorithm in a computationally efficient way.

5.2. Objective function optimization. To solve (3.2) in Algorithm 1, we employ an iterative algorithm, where a Stiefel manifold optimization is directly embedded into a parallelizable coordinate descent to update $\Gamma$ and $\Phi$ iteratively until convergence. This optimization algorithm is motivated by Qian et al. (2018) for SDR optimization problems with complete data, and is computationally efficient without inverting any large covariance. For presentation brevity, we leave the detailed algorithm and rationales in Supplement II.1.

6. Simulation studies. In this section, we evaluate the numerical performance of DASH along with the DS procedure for censored data in high dimension.

6.1. Performance with different covariance estimation. Unless stated otherwise, we use the following candidate parameters in our simulation and real data experiments: For $\tilde{\lambda}, \lambda, \tilde{\lambda}_1$ and $\lambda_1$, we use a sequence of 50 values between 0.01 and 1 that are evenly spaced in the logarithmic scale. Similarly, for $h_n$, we use a sequence of 20 values between 0.1 and 1 that are evenly spaced in the logarithmic scale. The candidates for $d_1$ and $d$ are $\{1, 2, 3\}$. In addition, we simply set $b_1 = b = 5$, $b_0 = 2$, $\tau_m = \text{median}(Y_i)$ and $\rho = 0.5$. Gaussian kernel was used for the estimation of $S(t \mid X)$ and $Q(t \mid X)$.

In the following, we set $n = 200$ and $p = 1000$. The covariate vector $X$ was generated from a multivariate normal distribution with mean zero and covariance matrix $\Sigma$ that has an exponential decay structure, such that $[\Sigma]_{i,j} = .5^{j-i}, i,j = 1, \ldots, p$. The survival time $T$ was generated from the linear transformation model $T = \exp(-2.5 + \beta^T X + 0.25 \varepsilon)$, where $\beta = (1, 1, 1, 1, 0, \ldots, 0)^T$, and the error $\varepsilon$ follows the standard extreme value distribution $\varepsilon = \log(-\log(1 - U))$ with uniformly distributed $U$ on $[0, 1]$. This corresponds to both an AFT and proportional hazards model. The censoring time $C$ was generated in two scenarios: Case 1: $C = \exp(-2 + \beta^T X + 0.5 \varepsilon_1)$; Case 2: $C = \exp(-1 + \beta_1^T X + 0.5 \varepsilon_1)$, where $\beta_1 = (0, \ldots, 0, 1, 1, 1, 1, 1)$, and $\varepsilon_1$ takes the extreme value distribution and is independent of $\varepsilon$. The censoring rates are on average about 27% for Case 1 and 40% for Case 2. It can be seen that in Case 1, $S_{T \mid X} = S_{(T,C) \mid X} = \text{Span}(\beta)$, and thus DS can be directly applied to estimate the target $S_{T \mid X}$, while in Case 2, $S_{T \mid X} = \text{Span}(\beta)$ is a proper subspace of $S_{(T,C) \mid X} = \text{Span}(\beta, \beta_1)$ and DASH is required to estimate the true central subspace.
We examined both DS and DASH in the high dimensional setting with covariance matrix $\Sigma$ estimated by sample covariance (SC) and thresholded covariance (TC), respectively. We denote them by SC-DS, SC-DASH, TC-DS and TC-DASH. The thresholded covariance is obtained by a univariate lasso-type thresholding rule in Rothman et al. (2009) designed for (approximately) sparse covariance matrix estimation. We recorded the estimated structural dimension $d$, and used Frobenius norm loss of projection matrix $\|P\hat{S}_{T|X} - P_{S_{T|X}}\|_F$ to evaluate the estimation accuracy of the central subspace. To quantify variable selection performance, we used $C_v$ to denote the number of correctly identified active variables, and $IC_v$ to denote the number of incorrectly identified active variables. The procedure above was repeated 100 times for each model and the results are summarized in Table 1.

The empirical results showed that when $S_{T|X} = S_{(T,C)|X}$ (Case 1), both methods successfully identified relevant variables with relatively low $IC_v$ rates, and correctly selected the structural dimension. As expected from the equivalence of $S_{T|X}$ and $S_{(T,C)|X}$ in this example, DS resulted in central subspace estimation similar to or slightly better than that of DASH. However, in Case 2 when $S_{T|X} \subset S_{(T,C)|X}$, DS tends to estimate the larger space $S_{(T,C)|X}$ and thus predominantly suggested larger structural dimensions than the truth of targeted $S_{T|X}$. Therefore, DS resulted in much higher estimation error in central subspace estimation and selected larger number of irrelevant variables than that of DASH. In practice, since the relationship between $S_{T|X}$ and $S_{(T,C)|X}$ is unknown, we suggest using the DASH method rather than simply stopping at double slicing: if the selected dimension of DASH is the same as that of DS, one may adopt results of DS for central subspace es-

\begin{table}[h]

\end{tabular}
\caption{Comparison of different estimations based on 100 runs.}
\end{table}
estimation and variable selection; on the other hand, if the selected dimension of DASH is smaller, we adopt final results from DASH. The thresholding covariance methods TC-DS and TC-DASH gave better estimation results than their sample covariance counterparts, suggesting potential gain by imposing the extra covariance thresholding step if covariance matrix is sparse.

6.2. Conditional quantile estimation. Since the proposed methods have the potential to facilitate nonparametric estimation of conditional survival functions and consequently conditional quantile functions, we further evaluated the numerical performance in estimating conditional quantile functions under nonlinear and heteroscedastic scenarios. Due to space constraint, we leave detailed numerical results in Supplement II.2.1.

6.3. Simulation examples with possible model misspecification. It is well-known that the Cox proportional hazard model requires the relative effect of covariates to be unchanged over time. Next we provide example case studies where this assumption does not hold. Specifically, with \( p = 1000 \), consider the following two hazard functions for \( T \): (Case A) \( h(t \mid X) = \exp(-2\beta^T X + |\beta^T X| t) \) and (Case B) \( h(t \mid X) = \exp(-(2+\beta_2^T X)^2 + (\beta_2^T X)^2 t) \), where \( \beta = (1, 1, 1, 0, \ldots, 0)^T \), \( \beta_2 = (1, 1, 0, \ldots, 0, 1)^T \), and \( X = (X_1, \ldots, X_p)^T \) consists of i.i.d. standard normal variables. Unless stated otherwise, our simulation sample size is set at \( n = 200 \). For both cases, we have \( \text{dim}(S_T \mid X) = 1 \), but the proportional hazard assumption is not satisfied. Indeed, for each case, its survival functions \( Q(t \mid x) \) at three different covariate values (denoted by \( x_1, x_2 \) and \( x_3 \)) are given in Figure 1, where \( x_1, x_2 \) and \( x_3 \) correspond to the first quartile, median and third quantile of \( \beta^T X \) (or \( \beta_2^T X \)) from a simulated data set. We observed the “crossing” pattern in both cases.

Fig 1: True survival functions \( Q(t \mid x) \) for some different covariate values \( x \). Left panel: Case A; Right panel: Case B

In the following, we consider various censoring time and covariate generat-
SDR FOR HIGH DIMENSIONAL CENSORED DATA

Due to space constraint, additional scenarios and related numerical results are left to Supplements II.2.2–II.2.6.

6.3.1. Large structural dimension $d_1$. First, for Case A, let $C = \exp(2 + \beta_3^T X + \varepsilon)$, where $\beta_3 = (1,1,1,0,\cdots,0)^T$ and $\varepsilon$ is the random error; for Case B, let $C = \exp(3 + \beta_4^T X + \varepsilon)$, where $\beta_4 = (0,\cdots,0,1,1,1)^T$. We consider two different choices of the random error (Lu & Li 2011): (PH) the extreme value distribution $\varepsilon = \log[-\log(1 - U)]$ and (PO) the logistic distribution $\varepsilon = \log[U/(1 - U)]$, where $U$ is uniform distribution on $[0,1]$. Both cases have $d_1 = \dim(S_{(T,C)|X}) = 2$, and we denote these censoring time scenarios by Case $A_0$ and Case $B_0$ respectively. In contrast, it is also possible to encounter scenarios with relatively large $d_1$. For example, for Case A, consider $C = \exp(2 + \beta_3^T X + 0.5X_4X_5 + 0.1X_6^2 + \varepsilon)$; for Case B, consider $C = \exp(3 + \beta_4^T X + 0.5X_4X_5 + 0.1X_6^2 + \varepsilon)$. Then both cases have $d_1 = 5$, and we denote them by Case $A_1$ and Case $B_1$, respectively.

When true $d_1$ is relatively large, as local KM method is involved in our estimation for conditional survival function of censoring time, by the curse of dimensionality and Theorem 4.2, it is expected that the use of a smaller (or underestimated) $d_1$ can often lead to better empirical results. Similar practice has been adopted in classical work of SDR survival models: for example, Xia et al. (2010) introduced a “working dimension” to find reduced space to apply kernel estimation for survival function of $Y$; Lu & Li (2011) applied a proportional hazard model to implement the estimation of survival function of $C$.

Accordingly, to illustrate the performance with possibly under-estimated $d_1$, we simply set $d_1 = 2$ for the DS step, which is correct for Cases $A_0$ and $B_0$ but is underestimated for Cases $A_1$ and $B_1$. Sample covariance estimation is used for both DS and DASH. The averaged simulation results over 100 runs summarized in Table 2 show that, like in Cases $A_0$ and $B_0$, DASH remains to perform reasonably well in both estimation and variable selection for Cases $A_1$ and $B_1$ despite our use of under-estimated $d_1$. In practice, a user may adopt the CV procedure of Section 5.1.2 to determine $d_1$ (DASH gives similar results and the details are thus omitted). On the other hand, the benchmark Coxnet method (Simon et al. 2011) does not give satisfactory results in these case studies.

In addition, we considered two other case examples (Case 5 and Case 6) with misspecified (under-estimated) $d_1$, which also showed reasonable numerical performance by DASH. We leave the detailed results including bootstrap confidence intervals in Supplement II.2.5 and Table II.3.
Table 2
Averaged simulation results with relatively large structural dimension $d_1$.

6.3.2. Approximately sparse central subspace. As seen from above, different from the penalized Cox model (Coxnet) or other partial likelihood related methods, our proposal does not assume the proportional hazard or require a specific model form, and is therefore intended to be robust to model misspecification in this perspective (which is different from the Coxnet’s robustness to model misspecification; e.g., Lu et al. 2012). In addition, as is pointed out in Remark 4.1, although we require sparsity in the central subspace, our proposal can be extended to an “approximately” sparse scenarios where a large number of variables are active for $S(T,C) \mid X$ but $S(T,C) \mid X$ can be approximated by a more sparse structure. In the following, we provide numerical illustration on the “approximately” sparse scenarios.

Modifying the settings in Section 6.3.1, under Case A of $T$, assume $C = \exp(2 + \tilde{\beta}_3^T X + \varepsilon)$, where $\tilde{\beta}_3 = \beta_3 + \frac{1}{\sqrt{m}} \delta_A$, and $\delta_A \in \mathbb{R}^p$ has its first 100 elements being 1 and the other elements being 0; denote this censoring time scenario by Case A$_2$. Similarly, under Case B of $T$, assume $C = \exp(3 + \tilde{\beta}_4^T X + \varepsilon)$, where $\tilde{\beta}_4 = \beta_4 + \frac{1}{\sqrt{m}} \delta_B$, and $\delta_B \in \mathbb{R}^p$ has its first and last 50 elements being 1 and the other elements being 0; denote this censoring time scenario by Case B$_2$. Set $m = 20, 100$ or 500. Clearly, larger $m$ indicates better approximation and smaller deviation of $S(T,C) \mid X$ in Case A$_2$ (or B$_2$) from the original sparsity structure in Case A$_0$ (or B$_0$). We kept
other simulation settings the same as that of Section 6.3.1, and summarized the results in Table 3.

Compared to Coxnet, the DASH method can still provide reasonable results in both estimation and variable selection even though some relevant variables got missed in estimation of the censoring time probability. Meanwhile, as the DASH estimation is partially influenced by the central subspace estimation errors in the first DS step, in alignment with Theorem 4.3, the DASH estimation errors tend to decrease as we decreased the relatively weak signals by increasing $m$ from 20 to 500. We expect similar phenomenon applies to approximately sparse scenarios for the survival time probability as well. To some extent, these numerical results provide some evidence that the DASH method may often be applicable when the central subspace violates the strict sparsity assumption and some relevant variables (with weak signals) are missed.

7. A real data example. In this section, we describe our analysis on the kidney renal clear cell carcinoma (KIRC) data, which was downloaded directly from the National Cancer Institute’s GDC Data Portal platform (https://portal.gdc.cancer.gov/) under project ID TCGA-KIRC. The KIRC data contains 530 patients with clinical information (including survival time and censoring time) as well as their gene expressions based on 57,251 genes from the next-generation sequencing technique known as RNA-Seq. Considering that RNA-Seq contains count data with unique structures including high skewness with many zeros, widely different sequencing depth and over-dispersion, we performed data pre-processing steps, the description of which is left in Supplement II.3. The cleaned data after pre-processing has \( p = 2962 \) genes and sample size \( n = 265 \) in both training and testing sets.

We then applied the proposed DASH method along with the DS procedure to the cleaned training set to obtain the estimated basis \( \hat{\Gamma}_0 \) and \( \hat{\Gamma}_1 \), respectively. We also applied the Coxnet method as a benchmark, which implicitly assumes \( d = 1 \) under the parametric Cox model. Both DS and DASH methods chose structural dimension \( d = 2 \), and the number of selected genes \( \#\text{Var} \) are given in Table 4, with DASH having the smallest model size among the three. In particular, we plot loadings of the two directions (denoted by DR1 and DR2) of \( \hat{\Gamma}_0 \) by a heatmap in Figure 2, with names of the selected genes marked under the corresponding cells. Interestingly, we found that multiple selected genes such as ENSG00000131778 (CHD1L, Cheng et al. 2013) and ENSG00000181449 (SOX2, Santini et al. 2014), among others, have been recently reported as useful prognostic biomarkers.

In the following, we show that the basis estimators of DS and DASH methods indeed performed well in predicting KIRC patient’s cancer prognosis. Specifically, with DS and DASH estimators given above, the sufficient
predictors had dimension $d = 2$, and we used the training data to build a gradient boosting machine (GBM; Friedman 2001), where a proportional hazard model $h(t \mid X) = h_0(t) \exp(R(Z_1, Z_2))$ is assumed with $(Z_1, Z_2)$ being the sufficient predictors, $R(Z_1, Z_2)$ is the general (nonlinear) link function that can be viewed as a patient’s risk score, and $h_0(t)$ is a base hazard function. The DASH link function surface in Figure 3 exhibited nonlinear patterns of the two sufficient predictors, as opposed to the linear assumption of Coxnet (the DS showed similar nonlinear patterns and is thus omitted).

![Graph](image)

**Fig 3:** Link function $R(Z_1, Z_2)$ from GBM using DASH predictors.

Using the models built above, we then computed the risk scores for all patients in the testing set and assigned them into the “high-risk” and “low-risk” groups using the median of the training-set risk scores as the cutoff. In Figure 4(a) and Figure 4(b), we plotted the testing-set KM estimator curves and their confidence interval curves of the two groups generated from DASH and DS methods, respectively. We also performed log-rank tests to compare survival functions of the two groups and showed $p$-values in Table 4. Both the KM curves and $p$-values obtained from our methods confirmed that the high-risk and low-risk groups segmented by the risk scores indeed had significantly different prognostic patterns.

Furthermore, we evaluated the risk scores computed above by the time-dependent receiver operating characteristic (ROC) curve analysis (Heagerty et al. 2000). Using median($Y$) of the training set as the cutoff time point, we considered sensitivity-specificity curves constructed using the testing set, and the corresponding areas under curve (AUC) are listed in Table 4. Satisfactorily, DS and DASH performed very competitively compared to the benchmark. It is not surprising that DS can perform well in this example given that it selected the same structural dimension as DASH. In addition, our evaluations on prediction performance showed similar patterns and advantages, the details of which are left in Supplement II.3.
8. Concluding remarks. We propose a promising model-free double-slicing assisted SDR method for high dimensional censored data, which is a flexible alternative to existing model-based approaches, such as high dimensional Cox models. The new development achieves simultaneous dimension reduction and variable selection while preserving full information for the distribution of $T \mid X$. With new technical tools to handle censored response, we establish both estimation consistency and variable selection consistency that allow $p$ to grow exponentially with $n$, and obtain uniform convergence for the nonparametric survival function estimation. As evidenced by numerical studies, our model-free proposal can greatly facilitate the practical application of robust nonparametric approaches in the estimation of conditional survival functions with high dimensional covariates.

APPENDIX A: PROPOSITIONS

Proposition A.1. Suppose the central subspace $S_{T \mid X}$ exists and is unique. Then the set of active variables $A_0$ for $S_{T \mid X}$ is also unique.

Proposition A.2. Given the objective function

(A.1) $F(\Gamma, \Phi) = \text{tr}\{ (U_c - \Sigma \Phi) \Sigma^{-1} (U_c - \Sigma \Phi) \}$, subject to $\Phi \Phi^T = I_d$,

where $\Gamma \in \mathbb{R}^{p \times d}$ and $\Phi \in \mathbb{R}^{d \times b}$ are parameters. Let $(\Gamma_0, \Phi_0)$ be any minimizer of (A.1). Then $\Gamma_0 \in \mathbb{R}^{p \times d}$ forms a basis matrix of $S_{T \mid X}$ and $\Phi_0$ is the corresponding coordinate matrix.
Proposition A.3. Let $A_0$ be the set of active variables for $S_T|X$ and let $\Gamma_0$ be a basis matrix of $S_T|X$. Then conditional on $X_{A_0}$ or $\Gamma_0^T X$, $T$ and $C$ are independent.

Proposition A.4. Let $\hat{\Xi} = \hat{\Gamma}_0 \hat{\Phi}_0$. Suppose $\hat{\Gamma}_0 \in \mathbb{R}^{p \times d}$ is the semi-orthogonal matrix consisting of left-singular vectors of $\hat{\Xi}$ with the nonzero singular values. If $\|\hat{\Xi} - \hat{U}_c\|_F \to 0$ as $n \to 0$ and Condition (C5) holds, then for large enough $n$, there exists a basis $\Gamma_0$ of $S_T|X$ such that

$$
\|\hat{\Gamma}_0 - \Gamma_0\|_F \leq \sqrt{2} \sin \Theta(S_\Xi, S_T|X) \leq c_a \|\hat{\Xi} - \hat{U}_c\|_F,
$$

where $c_a > 0$ is some constant, and $\Theta(S_\Xi, S_T|X)$ is $d \times d$ diagonal matrix in which the $j$th diagonal entry is the $j$th principle angle between $S_\Xi$ and $S_T|X$.

Proposition A.5. The coverage $S_{(Y, \delta)|X} \supseteq S_{(T, C)|X}$ holds if and only if $S_T|X \subseteq S_{(Y, \delta)|X}$ and $S_C|X \subseteq S_{(Y, \delta)|X}$.

Proposition A.6. Let $\Gamma_1$ be any minimizer of $\Gamma$ in (3.5). Given any index set $A \subset \{1, \cdots, p\}$, let $\Gamma_{1,A}$ be the $|A| \times d_1$ sub-matrix of $\Gamma_1$ consisting of the rows corresponding to $A$. Then given objective function (3.5) and an index set $A$, we have that $\|\Gamma_{1,A}\|_{2,1}$ is unique.

SUPPLEMENTARY MATERIALS

Supplement to “Double-Slicing Assisted Sufficient Dimension Reduction for High Dimensional Censored Data”: The supplemental file (Ding et al. 2019) contains proofs, technical details, and numerical results. Supplement I.1 gives proofs of the propositions; Supplement I.2 assembles some useful lemmas; Supplements I.3-I.5 provide proofs for the main theorems; Supplement II contains additional results on computation, simulation and data analysis.

ACKNOWLEDGEMENT
